Effectiveness of Positive Mindfulness Therapy and Emotion-Focused Cognitive-Behavioral Therapy in Improving Pain Perception and Sleep Quality in Fibromyalgia Patients

ABSTRACT

Aim: Pain is the most common mental pressure facing humans and one of the most common complaints among fibromyalgia patients. The present study aimed to investigate the effectiveness of Positive Mindfulness Therapy (PMT) and Emotion-Focused Cognitive-Behavioral Therapy (EFCBT) in improving pain perception and sleep quality in patients with fibromyalgia.

Method and Instruments: This study is a quasi-experimental research in which 60 referees who visiting Red Cross affiliated physiotherapy clinics in Tehran in 2020 were selected by convenience sampling and randomly divided into two experimental groups (positive mindfulness therapy and emotion-focused cognitive-behavioral therapy) and a control group (N=20 individuals per each group). The research instruments included the Pittsburgh Sleep Quality Index (PSQI) and the McGill Pain Questionnaire (MPQ). Data were analyzed using SPSS software version 20.

Findings: The results showed that PMT produced significant improvements in pain perception (P<0.001) and sleep quality (P=0.013) in the patients compared to the control group. Furthermore, EFCBT was effective in improving pain perception (P<0.001) and sleep quality (P=0.015) in fibromyalgia patients. The results did not imply a significant difference between the two treatment interventions.

Conclusions: Using PMT and EFCBT are effective in attenuating pain perception and improving sleep quality in fibromyalgia patients.

Keywords: Fibromyalgia, Pain Perception, Sleep Quality, Mindfulness, Emotional Cognitive

Introduction

Based on the WHO’s estimate, chronic diseases will be the leading cause of mortality and morbidity by 2025 and subsume two-third of all diseases. A surging number of chronic diseases in the health system will broaden governments’ focus on the importance of effective self-control in managing chronic diseases [1]. Fibromyalgia is a prevalent debilitating syndrome characterized by widespread and multifaceted musculoskeletal pain, multiple and unstable pain-sensitive points, sleep disturbance, fatigue, and muscle inflexibility [2]. Widespread body pain is the prominent characteristic of the disease, which may be delineated by such terms as sharp/burning, throbbing, aching/odd/deep, or tingling/numbness [3]. Fibromyalgia patients have lower pain tolerance than healthy individuals. Pain, particularly widespread odd and non-specific muscular pains, is the most common complaint in these patients. Fatigue, morning dryness, and headache are common in fibromyalgia patients [4].

Sleep, as one of the basic human needs, can cause psychological problems and reduce functionality when it is disturbed. The prevalence of sleep disturbances varies between 18% and 25% in the fibromyalgia population [5, 6]. Sleep disturbances are among...
psychological disorders with considerable weight in evaluating general and clinical health. They have a wide range of direct and indirect effects on functional status, quality of life, and productivity of people. Every year, chronic insomnia, as a common type of sleep disturbance, affects many individuals and their interpersonal relationships within their families and community [7, 8]. Casey et al. [9] showed that the majority of sleep disturbances collocate with other psychological disorders, complicating the patients’ condition; therefore, treating sleep disorders facilitates the improvement of accompanying psychological disorders. Zeichner et al. [10] reported that cognitive-behavioral disorders can improve sleep disturbances by 20%-40%.

Pain is the most important variable associated with fibromyalgia patients. The experience of pain is seen in either sensory or emotional fashions. The sensory and emotional dimensions reflect, respectively, the intensity of pain and the degree of unpleasant experience associated with it. Pain is probably the most common mental pressure facing humans and one of the most common complaints among patients [11, 12]. The International Association for the Study of Pain defines pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage [13].

In recent years and in line with psychological and spiritual factors related to pain and its outcomes, emotional regulation has been brought into theoretical and research fields as an important factor [14]. Among the approaches proposed by theorists, mental control is defined as similar to emotional control as a person’s control over his/her mind. Obviously, some spiritual teachings emphasize that spirituality reflects the mental teachings affected by surrounding factors; however, it is regarded as an important part of many teachings. Evidence shows the effectiveness of mental factors in improving disease and pain [12]. Kohrt et al. [15] showed the effectiveness of mental and spiritual factors in improving chronic pain. Kim et al. [16] showed the effectiveness of exercise (strength and flexibility exercises) and cognitive-behavioral interventions in attenuating chronic musculoskeletal conditions (fibromyalgia), improving performance, and changing secondary signs. Mohammadi Zeidi et al. [17] reported that training coping approaches, which are based on mental teachings, proved fruitful in enhancing health and easing clinical disorders.

By emphasizing self- and others-emotions identification skills (emotional awareness), proper expression of emotion based on social position (emotional understanding), reduction of negative emotions before triggering any response (emotional regulation), and cognitive-behavioral techniques, EFCBT can improve psychological symptoms, such as anxiety [18]. There is a recent surge in using this form of clinical interventions to improve psychological functions through combining and integrating traditional and religious exercises of mindfulness with common psychological techniques [19]. There are two forms of mindfulness-based clinical interventions, used extensively by researchers and clinicians: Mindfulness-Based Stress Reduction (MBSR) and Mindfulness-Based Cognitive Therapy (MBCT) [20, 21]. Based on the positive psychotherapy paradigm, these treatment interventions are not rejecting or substitute for traditional treatments. In other words, instead of undergoing a paradigm change, they intend to focus on strengths and weaknesses [22]. In fact, although some drug treatments have proven moderately fruitful in treating fibromyalgia, psychological treatments, such as Cognitive Behavioral Therapy (CBT), have
produced significant clinical improvement in the majority of these patients. As found in domestic literature, this is the first study on using EFCBT to treat fibromyalgia and the importance of comparing its effectiveness with that of common positive Mindfulness-Based Therapies (MBTs) in improving fibromyalgia. Accordingly, this study aimed to compare the effectiveness of positive mindfulness therapy and emotion-focused cognitive-behavioral therapy in improving pain perception and sleep quality in patients with fibromyalgia.

Method and Materials
This study is a quasi-experimental research in which 60 referees who visiting Red Cross affiliated physiotherapy clinics in Tehran in 2020 were selected by convenience sampling and randomly divided into two experimental groups (positive mindfulness therapy and emotion-focused cognitive-behavioral therapy) and a control group (N= 20 individuals per each group). The inclusion criteria were fibromyalgia diagnosis, the age range of 30-50 years, and at least high-school education. Participants were randomly divided into two experimental groups (Positive Mindfulness Training (PMT) and Emotion-Focused Cognitive-Behavioral Therapy (EFCBT)) and a control group (n=20 per group). After filling out the informed consent forms, the participants completed the McGill Pain Questionnaire (MPQ) and the Pittsburgh Sleep Quality Index (PSQI) in the pre-test stage. The participants were also ensured about the confidentiality of the results. After sampling, the intervention programs were performed separately for the experimental groups. During this period, the controls were not given any task to avoid probable interference with the results from the EFCBT and PMT groups. Harboring ethical considerations, a brochure containing intervention guidelines was provided to the controls after the post-test phase. After the implementation of the interventions to the experimental group, both the experimental and control groups underwent the post-test phase.

Research Instruments
Pittsburgh Sleep Quality Index (PSQI): The PSQI was used to measure sleep quality. This questionnaire has 7 subscales which are: subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleeping medication, and daytime dysfunction. This questionnaire originally contains nine items; however, since item 5 is comprised of 10 secondary items, the questionnaire has 19 items in total, which are scored on a 4-point Likert scale from 0 to 3. Finally, the total score is used to evaluate sleep quality. Afkham Ebrahimi et al. reported alpha Cronbach coefficient of 0.89 for the questionnaire. In the present study, the Cronbach's alpha coefficient was 0.84 for the questionnaire.

McGill Pain Questionnaire (MPQ): This questionnaire consists of 20 statements to evaluate individuals' perception of pain in different dimensions (namely Sensory, Affective, Evaluative, and Miscellaneous). The McGill Pain Questionnaire (MPQ) contains two independent measures: Sensory measure that describes the experience of pain and affective measure that describes the emotional dimension of the experience of pain. Items 1-10, 11-15, 16, and 17-20 are, respectively, the sensory, affective, evaluative, and miscellaneous descriptors of pain. Khosravi et al. reported the total Cronbach's alpha coefficients of this questionnaire to be 0.85 and Cronbach's alpha coefficients of each component to be >0.85 in their research. In the present study, the Cronbach's alpha coefficient was 0.82 for the questionnaire.

Intervention program
The first intervention program consisted of eight 90-minute sessions of PMT [28]. (Table 1 presents summary of sessions). The second intervention program consisted of ten 90-minute sessions of EFCBT [29]. (Table 2 presents summary of sessions).

Data were analyzed at descriptive and inferential levels using SPSS version 20. The mean and standard deviation were used at the descriptive level. The Bonferroni post-hoc test and MANCOVA were used at the inferential level following investigating the presumptions of this analysis. Before conducting the MANCOVA, Shapiro-Wilk and Levene’s test were used to assess, respectively, data normality and homogeneity of variance; in addition, the equality of regression lines was investigated through examining the interaction between test and group membership.

Findings

The participants included 60 patients with fibromyalgia. The mean age of the participants in the mindfulness, cognitive-behavioral, and control groups were 43.3±6.72, 42.8±7.08, and 42.9±5.86 years old, respectively. Table 3 shows the demographic variables of the participants in the experimental and control groups. Moreover, Table 4 shows the descriptive indices of the research variables in these
The Kolmogorov-Smirnov test was used to examine the assumed normality of data. Table 5 shows the results of the Kolmogorov-Smirnov test used to investigate the assumed normality of data. According to Table 5, the distribution of dependent variables, including pain perception and sleep quality, was normal in both the pre-test and post-test phases, confirming the assumed normality of dependent variables (P> 0.05).

The Bonferroni post-hoc test was used to compare the effectiveness of PMT and EFCBT in pain perception and sleep quality of fibromyalgia patients. Table 6 shows the Bonferroni test results on the difference in

SD: Standard deviation
mean scores of the groups in pain perception and sleep quality in the post-test phase. According to Table 6, significant differences exist in the pain perception and sleep quality scores between the PMT and EFCBT groups with the control group (P< 0.05). PMT significantly reduced pain perception among patients with fibromyalgia (P= 0.001). The results also indicate that the PMT and EFCBT significantly increased sleep quality in patients with fibromyalgia (P< 0.05). Table 5 did not show a significant difference between the experimental groups in pain perception. There was not any significant difference in the effectiveness of PMT and EFCBT in improving pain perception. There was not any significant difference in the mean score of sleep quality between the
experimental groups. There was not any significant difference in the effectiveness of PMT and EFCBT in improving sleep quality.

Discussion
The present study aimed to investigate the effectiveness of PMT and EFCBT in improving pain perception and sleep quality in patients with fibromyalgia. The results showed that PMT and EFCBT produced significant improvements in pain perception and sleep quality in the patients compared to the control group. It can be concluded that these intervention methods affected dependent variables. This finding is consistent with the results of Prados et al. [30] and Amutio et al. [31]. Emotion-focused therapy is concentrated on emotion scheme processes and sets emotional processing as its fundamental treatment goal. Using emotion-focused approaches can increase the use of positive emotion regulation approaches, thereby reducing the use of negative emotion regulation approaches [32]. This therapy contributes to enhancing emotional skills and forming an effective mental pattern and leads to transparency and emotional regulation by validating emotions.

Based on cognitive theories, bias is associated with various dysfunctional cognitions which, in turn, trigger maladaptive behavioral and emotional responses. Moreover, mindfulness-based therapy not only helps individuals discover deep senses of comfort and satisfaction, integrate them with daily life, and convert them into lifestyle, but also helps them to gradually get free from the states of worry, anxiety, fatigue, depression, and dissatisfaction. This approach believes that everyone undergoes periods of suffering and pain. A mindfulness-based approach turns these pain and suffering into empathetic suffering, which leads to the feeling of self-compassion and others-compassion; whereas, these feelings of pain and suffering are experienced as exhausting emotions that are integrated with anger and helplessness [33]. It can thus be said that these techniques are effective in improving pain perception and sleep quality of fibromyalgia patients.

The results showed that there was not any significant difference between these treatment interventions in improving sleep quality and pain perception. The presence of the mind helps patients neutralize the development of the physical feelings and sensations at a suitable time through facilitating the identification of thought patterns. This way of awareness-raising enables patients to more clearly observe the development of rumination and negative reactions and then decentralize such patterns. Generally, a cognitive therapy premised on the presence of mind aims at enabling patients to harbor their thoughts only as pure thoughts and examinable mental events. It also enables them to separate the occurrence of negative mental events from responses they induce and finally change their meanings. In many cases, the pain is transient and responds to consolation with/without analgesics. When a psychological disorder is diagnosed, the attention should be shifted from pain symptomology and a suitable treatment should be implemented at the same time [34]. Therefore, it is hoped that the pain and the disease are eliminated together. Research limitations included the age range of 30-50 years, non-generalizability of the results to patients in other cities, and limited information of fibromyalgia patients.

Conclusion
According to the results, PMT and EFCBT are effective in attenuating pain perception and improving sleep quality in fibromyalgia patients. Moreover, there is not any significant difference in the effectiveness of these two treatment interventions. It is then
recommended to conduct this research on fibromyalgia patients. Future studies are recommended to have a follow-up stage. It is also recommended to hold PMT and EFCBT workshops to reduce pain and improve sleep quality.
